## Abstract

The Particle Data Group decided to split the  $\eta(1440)$  into two states, called  $\eta_L$  and  $\eta_H$ . The  $\eta(1295)$  and the  $\eta_H$  are supposed to be the radial excitations of the  $\eta$  and  $\eta'$ , respectively. The  $\eta_L$  state cannot be accommodated in a quark model; it cannot be a  $q\bar{q}$  state, however, it might be a glueball. In this contribution it is shown that the  $\eta(1295)$  does not have the properties which must be expected for a radially excited state. The splitting of the  $\eta(1440)$  is traced to a node in the wave function of a radial excitation. Hence the two peaks,  $\eta_L$  and  $\eta_H$ , originate from one resonance which is interpreted here as first radial excitation of the  $\eta$ .

## 1 Short history of the $\eta(1440)$

The E/ $\iota$  was discovered in 1967 in  $p\bar{p}$  annihilation at rest into  $(K\bar{K}\pi)\pi^+\pi^-$ . It was the first meson found in a European experiment and was called E-meson [1]. Mass and width were determined to be  $M = 1425 \pm 7, \Gamma = 80 \pm 10$  MeV, with quantum numbers  $J^{PC} = 0^{-+}$ . In the charge exchange reaction  $\pi^-p \rightarrow nK\bar{K}\pi$ , using a 1.5 to 4.2 GeV/c pion beam [2], a state was observed with  $M = 1420 \pm 20, \Gamma = 60 \pm 20$  MeV and  $J^{PC} = 1^{++}$ . Even though the quantum numbers were different, it was still called E-meson.

In 1979 there was a claim [3] for the  $\eta(1295)$  which was later confirmed in other experiments. In 1980 the E-meson was observed [4] in radiative J/ $\psi$  decays into  $(K\bar{K}\pi)$  with  $M = 1440 \pm 20, \Gamma = 50 \pm 30$  MeV; the quantum numbers were ‘rediscovered’ [5] to be  $J^{PC} = 0^{-+}$ . The E-meson was renamed  $\iota(1440)$  to underline the claim that it was the  $\iota^{\text{st}}$  glueball discovered in an experiment. The  $\iota(1440)$  is a very strong signal, one of the strongest, in radiative J/ $\psi$  decays. The radial excitation  $\eta(1295)$  is not seen in this reaction; hence the  $\iota(1440)$  must have a different nature. At that time it was proposed (and often still is) to be a glueball. Further studies, in particular by the Obelix collaboration at LEAR [7], showed that the  $\iota(1440)$  is split into two components, a  $\eta_L \rightarrow a_0(980)\pi$  with  $M = 1405 \pm 5, \Gamma = 56 \pm 6$  MeV and a  $\eta_H \rightarrow K^*\bar{K} + \bar{K}^*K$  with  $M = 1475 \pm 5, \Gamma = 81 \pm 11$  MeV: there seem to be 3  $\eta$  states in the mass range from 1280 to 1480 MeV.

The  $\eta(1295)$  is then likely the radial excitation of the  $\eta$ . It is mass degenerate with the  $\pi(1300)$ , hence the pseudoscalar radial excitations seem to be ideally mixed. Then, the  $\bar{s}s$  partner should have a 240 MeV higher mass. The  $\eta_H$  could play this role. The  $\eta_L$  does not find  $\eta_L$  a slot in the spectrum of  $\bar{q}q$  mesons; the low mass part of the  $\iota(1440)$  could be a glueball. This conjecture is consistent with the observed decays. A pure flavor octet  $\eta(xxx)$  state decays into  $K^*K$  but not into  $a_0(980)\pi$ . In turn, a pure flavor singlet  $\eta(xxx)$  state decays into  $a_0(980)\pi$  but not into  $K^*K$ . The  $\eta_H$ , with a large coupling to  $K^*K$ , cannot possibly be a glueball, whereas the  $\eta_L$  with its  $a_0(980)\pi$  decay mode can be.

The PDG 2004 supports this interpretation of the pseudoscalar mesons [8]:

$\pi$	$\eta$		$\eta'$	$K$
$\pi(1300)$	$\eta(1295)$	$\eta(1405)$	$\eta(1475)$	$K(1460)$
$n\bar{n}$	$n\bar{n}$	glueball	$s\bar{s}$	$n\bar{s}$

Two quantitative tests have been proposed to test if a particular meson is glueball-like: the stickiness and the gluiness. The stickiness of a resonance R with mass  $m_R$  and two-photon width  $\Gamma_{R \rightarrow \gamma\gamma}$  is defined as:

$$S_R = N_l \left( \frac{m_R}{K_{J \rightarrow \gamma R}} \right)^{2l+1} \frac{\Gamma_{J \rightarrow \gamma R}}{\Gamma_{R \rightarrow \gamma\gamma}},$$

where  $K_{J \rightarrow \gamma R}$  is the energy of the photon in the J rest frame,  $l$  is the orbital angular momentum of the two initial photons or gluons ( $l = 1$  for  $0^-$ ),  $\Gamma_{J \rightarrow \gamma R}$  is the J radiative decay width for R, and  $N_l$  is a normalization factor chosen to give  $S_\eta = 1$ . The L3 collaboration determined [9] this parameter to be  $S_{\eta(1440)} = 79 \pm 26$ .

The gluiness ( $G$ ) was introduced [10,11] to quantify the ratio of the two-gluon and two-photon coupling of a particle and is defined as:

$$G = \frac{9 e_q^4}{2} \left( \frac{\alpha}{\alpha_s} \right)^2 \frac{\Gamma_{R \rightarrow gg}}{\Gamma_{R \rightarrow \gamma\gamma}},$$

where  $e_q$  is the relevant quark charge.  $\Gamma_{R \rightarrow gg}$  is the two-gluon width of the resonance R, calculated from equation (3.4) of ref. [10]. Stickiness is a relative measure, gluiness is a normalised quantity and is expected to be near unity for a  $q\bar{q}$  meson. The L3 collaboration determined [9] this quantity,  $G_{\eta(1440)} = 41 \pm 14$ .

These numbers can be compared to those for the  $\eta'$  for which  $S_{\eta'} = 3.6 \pm 0.3$  and  $G_{\eta'} = 5.2 \pm 0.8$  is determined, for  $\alpha_s(958 \text{ MeV}) = 0.56 \pm 0.07$ . Also  $\eta'$  is 'gluish', but much more the  $\eta_L$ . The  $\eta_L$  is the first glueball!

## 2 The $\eta(1295)$ and the $\eta(1440)$ in radiative $J/\psi$ decays

Radiative  $J/\psi$  decays show an asymmetric peak in the  $\eta(1440)$  region therefore both the  $\eta_L$  and the  $\eta_H$ , must contribute to the process. Obviously, radial excitations are produced in radiative  $J/\psi$  decays (not only glueballs). The  $\eta(1295)$  must therefore also be produced, but it is not - at least not with the expected yield. Is there evidence for this state in other reactions?

At BES,  $\eta(1295)$  and  $\eta(1440)$  were studied in  $J/\psi \rightarrow (\rho\gamma)\gamma$  and  $\rightarrow (\phi\gamma)\gamma$  [12]. The  $\eta(1440)$  (seen at 1424 MeV) is seen to decay strongly into  $\rho\gamma$  and not into  $\phi\gamma$ . This is not consistent with the hypothesis of  $\eta(1475)$  being a  $s\bar{s}$  state. A peak below 1300 MeV is assigned to the  $f_1(1285)$  even though a small contribution from  $\eta(1295)$  cannot be excluded.

### 3 The $\eta(1295)$ and the $\eta(1440)$ in $\gamma\gamma$ at LEP

Photons couple to charges; in  $\gamma\gamma$  fusion a radial excitation is hence expected to be produced more frequently than a glueball. In  $\gamma\gamma$  fusion, both electron and positron scatter by emitting a photon. If the momentum transfer to the photons is small, the  $e^+$  and  $e^-$  are scattered into forward angles (passing undetected through the beam pipe), thus the two photons are nearly real. If the  $e^+$  or  $e^-$  has a large momentum transfer, the photon acquires mass, and we call the process  $\gamma\gamma^*$  collision. Two massless photons couple to the  $\eta(1295)$  but not to the  $f_1(1285)$ ; in this way, a peak at  $\sim 1290$  MeV can be identified as one of the two states. The L3 collaboration studied  $\gamma\gamma^*$  and  $\gamma\gamma \rightarrow K_s^0 K^\pm \pi^\mp$ . At low  $q^2$ , a peak at 1440 MeV is seen, it requires high  $q^2$  to produce a peak at 1285 MeV. A pseudoscalar state is produced also at vanishing  $q^2$  while  $J^{PC} = 1^{++}$  is forbidden for  $q^2 \rightarrow 0$ . Hence the structure at 1285 MeV is due to  $f_1(1285)$  and not due to  $\eta(1295)$ . There is no evidence for  $\eta(1295)$  from  $\gamma\gamma$  fusion. The stronger peak contains contributions from  $\eta(1440)$  and  $f_1(1420)$  [9]. The coupling of the  $\eta(1440)$  meson to photons is stronger than that of the  $\eta(1295)$ : the assumption that the  $\eta(1295)$  is a  $(u\bar{u} + d\bar{d})$  radial excitation must be wrong!

### 4 The $\eta(1295)$ and $\eta(1440)$ in $p\bar{p}$ annihilation

The Crystal Barrel collaboration searched for the  $\eta(1295)$  and  $\eta(1440)$  in the reaction  $p\bar{p} \rightarrow \pi^+\pi^-\eta(xxx)$ ,  $\eta(xxx) \rightarrow \eta\pi^+\pi^-$ . The search was done by assuming the presence of a pseudoscalar state of given mass and width, mass and width are varied and the likelihood of the fit is plotted. Fig. 1 shows such a plot [13]. A clear pseudoscalar resonance signal is seen at 1405 MeV. Two decay modes are observed,  $a_0(980)\pi$  and  $\eta\sigma$  with a ratio  $0.6 \pm 0.1$ . We use the notation  $\sigma$  for the full  $\pi\pi$  S-wave.

A scan for an additional  $0^+0^-$  resonance provides no evidence for the  $\eta(1295)$  but for a second resonance at 1480 MeV, see Fig. 1, with  $M = 1490 \pm 15$ ,  $\Gamma = 74 \pm 10$ . This is the  $\eta_H$ . It decays to  $a_0(980)\pi$  and  $\eta\sigma$  with a ratio  $0.16 \pm 0.10$ . This data provides the first evidence for  $\eta_H \rightarrow \eta\pi\pi$  decays.

The phenomena observed in the pseudoscalar sector are confusing: The  $\eta(1295)$ , the assumed radial excitation of the  $\eta$ , is only seen in  $\pi^-p \rightarrow n(\eta\pi\pi)$ , not in  $p\bar{p}$  annihilation, nor in radiative  $J/\psi$  decay, nor in  $\gamma\gamma$  fusion. In all these reactions it should have been observed. There is no reason for it to have not been produced if it is a  $\bar{q}q$  state. On the other hand, we do not expect glueballs, hybrids or multiquark states so low in mass. In the 70's, the properties of the  $a_1(1260)$  were obscured by the so-called Deck effect ( $\rho$ - $\pi$  re-scattering in

Figure 1. Scan for a  $0^+0^{-+}$  resonance with different widths [13]. The likelihood optimizes for  $M = 1407 \pm 5$ ,  $\Gamma = 57 \pm 9$  MeV. The resonance is identified with the  $\eta_L$ . A search for a second pseudoscalar resonance (right panel) gives evidence for the  $\eta_H$  with  $M = 1490 \pm 15$ ,  $\Gamma = 74 \pm 10$  MeV.

the final state). Possibly,  $a_0(980)\pi$  re-scattering fakes a resonant-like behavior but the  $\eta(1295)$  is too narrow to make this possibility realistic. Of course there is the possibility that the  $\eta(1295)$  is mimicked by feed-through from the  $f_1(1285)$ . In any case, I exclude the  $\eta(1295)$  from the further discussion.

The next puzzling state is the  $\eta(1440)$ . It is not produced as  $\bar{s}s$  state but decays with a large fraction into  $K\bar{K}\pi$  and it is split into two components. I suggest that the origin of these anomalies is due to a node in the wave function of the  $\eta(1440)$ ! This node has an impact on the decay matrix elements calculated by Barnes *et al.* [14] within the  $^3P_0$  model.

## 5 $E/\iota$ decays in the $^3P_0$ model

The matrix elements for decays of the  $\eta(1440)$  as a radial excitation ( $=\eta_R$ ) depend on spins, parities and decay momenta of the final state mesons. For  $\eta_R$  decays to  $K^*K$ , the matrix element is given by

$$f_P = \frac{2^{9/2} \cdot 5}{3^{9/2}} \cdot x \left(1 - \frac{2}{15}x^2\right).$$

In this expression,  $x$  is the decay momentum in units of 400 MeV/c; the scale is determined from comparisons of measured partial widths to model predictions. The matrix element vanishes for  $x = 0$  and  $x^2 = 15/2$ , or  $p = 1$  GeV/c. These zeros have little effect on the shape of the resonance.

The matrix element for  $\eta_R$  decays to  $a_0(980)\pi$  or  $\sigma\eta$  has the form

$$f_S = \frac{2^4}{3^4} \cdot \left(1 - \frac{7}{9}x^2 + \frac{2}{27}x^2\right)$$

and vanishes for  $p = 0.45 \text{ GeV}/c$ . The decay to  $a_0(980)\pi$  vanishes at the mass 1440 MeV. This has a decisive impact on the shape, as seen in Figure 2. Shown are the transition matrix elements as given by Barnes et al. [14] and the product of the squared matrix elements and a Breit–Wigner distribution with mass 1420 MeV and width 60 MeV.

Figure 2. Amplitudes for  $\eta(1440)$  decays to  $a_0\pi$  (first row),  $\sigma\eta$  (second row), and  $K^*\bar{K}$  (third row); the Breit-Wigner functions are shown on the left, then the squared decay amplitudes [14] and, on the right, the resulting squared transition matrix element.

The  $\eta(1440) \rightarrow a_0(980)\pi$  and  $\rightarrow K^*K$  mass distributions have different peak positions; at approximately the  $\eta_L$  and  $\eta_H$  masses. Hence there is no need to introduce the  $\eta_L$  and  $\eta_H$  as two independent states. One  $\eta(1420)$  and the assumption that it is a radial excitation describe the data.

This conjecture can be further tested by following the phase motion of the  $a_0(980)\pi$  or  $\sigma\eta$  isobar [13]. The phase changes by  $\pi$  and not by  $2\pi$ , see Fig. 3.

## 6 Conclusions

Summarizing, the results for the radial excitations of pseudoscalar mesons are as follows:

- The  $\eta(1295)$  is not a  $q\bar{q}$  meson.
- The  $\eta(1440)$  wave function has a node leading to two apparently different states  $\eta_L$  and  $\eta_H$ .

Figure 3. Complex amplitude and phase motion of the  $a_0(980)\pi$  isobars in  $p\bar{p}$  annihilation into  $4\pi\eta$ . In the mass range from 1300 to 1500 MeV the phase varies by  $\pi$  indicating that there is only one resonance in the mass interval. The  $\sigma\eta$  (not shown) exhibits the same behavior [13].

- There is only one  $\eta$  state, the  $\eta(1420)$ , in the mass range from 1200 to 1500 MeV and not 3!
- The  $\eta(1440)$  is the radial excitation of the  $\eta$ . The radial excitation of the  $\eta'$  is expected at about 1800 MeV; it might be the  $\eta(1760)$ .

The following states are most likely the pseudoscalar ground states and radial excitations:

$1^1S_0$	$\pi$	$\eta'$	$\eta$	K
$2^1S_0$	$\pi(1300)$	$\eta(1760)$	$\eta(1440)$	K(1460)
